Abstract

The selective ¹⁵N isotope labeling was used for the identification of the nitrogen involved in an hydrogen bond formation with the semiquinone in the high-affinity Q_H site in the cytochrome *bo*₃ ubiquinol oxidase. This nitrogen produces dominating contribution to X-Band ¹⁴N ESEEM spectra. The 2D ESEEM (HYSCORE) experiments with the Q_H site SQ in the series of selectively ¹⁵N labeled *bo*₃ oxidase proteins have directly identified the N_ε of R71 as an H-bond donor. In addition, selective ¹⁵N labeling has allowed us for the first time to determine weak hyperfine couplings with the side-chain nitrogens from all residues around the SQ. Those are reflecting a distribution of the unpaired spin density over the protein in the SQ state of the quinone processing site.

E. coli cytochrome (cyt) *bo*₃ ubiquinol oxidase catalyzes the two-electron oxidation of ubiquinol and the four-electron reduction of O₂ to water. The enzyme contains three redox-active metal centers: a low spin heme *b*, which is involved in quinol oxidation, and the heme *o*₃/Cu_B bimetallic center, which is the site where O₂ binds and is reduced to water. The ubiquinol oxidation occurs with a semiquinone (SQ) intermediate in an overall reaction that releases two protons to the periplasm. The enzyme contains two Q sites¹⁻⁶: a low affinity site (Q_L), which is equilibrated with the quinone pool in the membrane and functions as the substrate (QH₂) binding site, and a high affinity (Q_H) site, from which Q is not readily removed, and which stabilizes a SQ.⁷⁻¹⁰ The Q_H site quinone appears to function as a tightly bound cofactor, similar to the Q_A site of the reaction centers. The X-ray structure of cyt *bo*₃¹¹ does not contain any bound quinone, but mutational substitutions of R71, D75, H98, and Q101

modulate the properties of the Q_H site, forming the basis of a model of Q_H binding site (see Supporting Info).^{2-4,11}

The interaction of the SQ with the protein environment in cyt *bo*₃ has been studied by pulsed EPR spectroscopy. X-band ESEEM data show that there is one H-bond to the Q_H SQ from a nitrogen donor.^{5,6,12,13} The speculated identification of this nitrogen has been based on the quadrupole coupling constant (qcc) determined from the ESEEM spectra.^{5,6,12,13} Its value, $K=e^2qQ/4h=0.93$ MHz, most closely corresponds to the nitrogen from an NH or NH₂ group.^{12,13} This value is ~10% larger than the qcc for the peptide amide nitrogen and significantly exceeds the qcc of the protonated nitrogens in histidine. Hence, the most likely candidates for the H-bond donor are the nitrogens from the side chains of R71 or Q101, though a peptide backbone nitrogen cannot be ruled out completely.

To overcome the existing uncertainties and to identify directly the H-bonded nitrogen, we employed ¹⁵N selective labeling in different residues. Proteins were labeled as follows: 1) ¹⁵N uniformly labeled Arg; 2) ¹⁵N uniformly labeled His; 3) Gln with ¹⁵N only in the N_ϵ position; 4) Arg with ¹⁵N only in the two N_η positions; 5) Arg with ¹⁵N only in the peptide nitrogen (Scheme 1). The ¹⁵N labeling procedures, the preparation of EPR samples and generation of the SQ are described in Supporting Info. To resolve the interaction of the SQ with ¹⁴N and ¹⁵N nitrogens we used X-band three-pulse ESEEM and 2D ESEEM (HYSCORE).

The X-band three-pulse ¹⁴N ESEEM spectrum of the SQ in wild-type cyt *bo*₃ has been described in detail previously.^{5,6,12,13} It consists of three-intensive narrow lines: $\nu_0=0.95$ MHz, $\nu_- =2.32$ MHz, and $\nu_+=3.27$ MHz, where $\nu_+ =\nu_0 + \nu_-$. There is also a less intensive and broader line at frequency $\nu_{dq} \sim 5.1$ -5.2 MHz (see Supporting Info). This spectrum is typical for a single ¹⁴N at near cancellation conditions ($|\nu_N - A/2| \sim 0$; ν_N – ¹⁴N Zeeman frequency, ~1.07 MHz in X-band, A – hyperfine coupling). The narrow peaks are assigned to the three nuclear quadrupole resonance frequencies, and broader line is the frequency of the double-quantum transition ν_{dq} from the opposite manifold. The spectroscopic parameters determine the qcc $K=0.93$ MHz, the asymmetry parameter $\eta=0.51$, and the hyperfine coupling $A = 1.8$ MHz for this nitrogen.^{5,6,12,13} The corresponding HYSCORE spectrum of the SQ in wild-type *bo*₃ (Fig. 1a) exhibits cross-peaks correlating ν_0 , ν_- , and ν_+ with ν_{dq} , thus indicating that they belong to different manifolds. The most intensive cross-peaks in Fig. 1a are from the (ν_+ , ν_{dq}) correlations. There are also three intensive peaks at the diagonal points corresponding to ν_0 , ν_- , and ν_+ .

Specifically, the ¹⁵N-labeled proteins were examined in order to identify the nitrogen responsible for the ¹⁴N features observed with wild-type protein. It is assumed that only R71, Q101 and H98 are significant in interpreting the results from ¹⁵N-labeled Arg, Gln and His residues, respectively. Fig. 1b shows the spectrum of *bo*₃ with ¹⁵N-labeled N_η in R71. In addition to the unchanged ¹⁴N features, this spectrum resolves two new weak cross-peaks from ¹⁵N centered around a diagonal point with a ¹⁵N Zeeman frequency $\nu_N \sim 1.5$ MHz with coordinates (1.58, 1.43) MHz corresponding to the hyperfine coupling $^{15}A=0.15$ MHz. The spectrum of the *bo*₃ with ¹⁵N labeled N_p of R71 did not show any resolved peaks from ¹⁵N. A peak of very low intensity located at the diagonal point ($^{15}\nu_N, ^{15}\nu_N$) was observed for the *bo*₃ with labeled N_ϵ of Q101, thus indicating very weak dipolar interaction between the unpaired electron and a distant ¹⁵N nucleus. The spectrum of the *bo*₃ with uniformly ¹⁵N-labeled H98 (Fig. 1c) also shows the peak with a maximum at the diagonal point ($^{15}\nu_N, ^{15}\nu_N$). However, it is accompanied by extended shoulders with weakly resolved maxima corresponding to couplings of ~0.3 and 0.6 MHz. This line can be produced by the interactions with up to three ¹⁵Ns, and more specific labeling will be needed to resolve the exact coupling from each nitrogen of this residue. The spectra of these samples have clearly shown that labeled nitrogens in each of the residues R71 (except N_p), Q101 and H98 are located in close proximity of the

paramagnetic SQ and some of them even carry a small fraction of the unpaired spin density producing isotropic hyperfine splittings of ~ 0.1 to 0.6 MHz. However, none of these ^{15}N -labeled positions is responsible for the X-band ^{14}N ESEEM features of the wild-type protein which would result in a significantly larger ^{15}N hyperfine coupling, $^{15}\text{A} \sim 2.5$ MHz (recalculated from $\text{A} \sim 1.8$ MHz for ^{14}N).

A dramatic change of the ESEEM spectra, accompanied by the complete disappearance of the ^{14}N peaks, is observed in the bo_3 with uniformly ^{15}N -labeled R71 (Fig 1d). The HYSCORE spectrum of the SQ in this protein contains two intense cross-peaks (N_ϵ) from ^{15}N with a maximum at $(2.74, 0.34)$ MHz corresponding to the coupling $^{15}\text{A} = 2.4$ MHz, as well as weak features similar to ones observed for R71 with $^{15}\text{N}_\eta$ s (Fig. 1b). The extended shape of the N_ϵ peaks results from the anisotropic hyperfine interaction with the average perpendicular component of the tensor $T \sim 0.4$ MHz. Taking into account that R71, selectively labeled in the N_η and N_ρ positions, does not result in features correlating to a large hyperfine coupling, it can be definitively concluded that the N_ϵ of R71 is an H-bond donor to the carbonyl oxygen of the SQ. The unpaired spin density fraction of $\sim 1.2 \cdot 10^{-3}$ is transferred onto the N_ϵ nucleus through the H-bond bridge (see Supporting Info). Spin density delocalization continues further through N_ϵ and reaches at least one N_η , which is separated by two bonds from the N_ϵ in the side-chain, producing the resolved coupling $^{15}\text{A} \sim 0.15$ MHz.

These experiments also provide evidence that some unpaired spin density (^{15}A coupling up to 0.6 MHz) is transferred to the nitrogens of H98, suggesting its involvement in an H-bond with a larger O-H bond distance or with a less favorable configuration of the spin density transfer than the H-bond with the N_ϵ of R71. The weakly coupled nitrogens with $^{15}\text{A} < 0.6$ MHz ($^{14}\text{A} < 0.43$ MHz) are far away from the cancellation condition and, as a result, do not produce resolved contributions to the X-band 1D and 2D ^{14}N ESEEM spectra. The evidence also supports a weak interaction of the SQ with the side chain nitrogen of Q101.

In summary, the experiments with the Q_H site SQ in the series of selectively ^{15}N labeled bo_3 oxidases have directly identified the N_ϵ of R71 as the H-bond donor responsible for the features observed in the X-band ^{14}N ESEEM of wild-type bo_3 . In addition, selective ^{15}N labeling has allowed us for the first time to probe a distribution of the unpaired spin density on the side-chain nitrogens from the residues around the SQ in the quinone binding site. These results form a basis for more advanced theoretical analysis of the protein-SQ interaction in the Q_H site, using the model of the neutral radical indicated by the proton hyperfine couplings^{12,13}, in conjunction with other available magnetic resonance data.¹⁴
